Murine Models of Splenic Marginal Zone Lymphoma: A Role for *Cav1*?

Chelsey L. Patten and Christine E. Cutucache*

University of Nebraska at Omaha, Omaha, NE, USA

Dozens of murine models of indolent and aggressive B-cell lymphomas have been generated to date. These include those manifesting chronic lymphocytic leukemia (CLL), diffuse large B-cell lymphoma (DLBCL), as well as xenografts of mantle cell lymphoma (MCL). These models have led to an improved understanding of disease etiology, B-cell biology, immunomodulation, and the importance of the tumor microenvironment. Despite these efforts in CLL, DLBCL, and MCL, considerably little progress toward a model of splenic marginal zone lymphoma (SMZL) has been accomplished. Herein, we describe the similarities and differences between CLL, MCL, and SMZL and highlight effective murine models that mimic disease in the two former, in hopes of informing a potential model of the latter. At the time of writing this review, the precise molecular events of SMZL remain to be determined and a treatment regimen remains to be identified. Therefore, based on the efforts put forth in the B-cell lymphoma field throughout the past three decades, the established role of *caveolin-1* in B- and T-cell biology as an oncogene or tumor suppressor, and the recurrent deletion or loss of heterozygosity (LOH) of 7q in many cancers, we make recommendations for a murine model of SMZL.

Keywords: splenic marginal zone lymphoma, 7q minimally deleted region, 7q LOH, genetically engineered, neoplasms

BACKGROUND

Splenic marginal zone lymphoma (SMZL) is a newly acknowledged cancer that effects primarily middle-aged and elderly patients. This disease primarily effects patients ages 60 and older without evidence of gender predominance (1). Since SMZL is less than a quarter-century old in terms of recognition by the World Health Organization, little progress has been made regarding disease pathogenesis.

Although multiple B-cell lymphoma murine models have been created, currently there is no mouse model dedicated specifically to understanding the disease pathology of SMZL. With no definitive clues as to what drives this disease, the development of a reliable and replicable *in vivo* model is needed in order to understand the basic oncogenic factors leading to SMZL. In this review, we discuss possible contributing factors in tumorigenesis, highlight three similar B-cell malignancies [i.e., chronic lymphocytic leukemia (CLL), mantle cell lymphoma (MCL), and SMZL]—including their shared immunophenotype, as well as currently existing murine models of these neoplasms—and finally we discuss the role for 7q in SMZL. Ultimately, we make a recommendation for the generation of a murine model with a knockout at 7q involving *caveolin-1* (*CAV1*), based on its role in related B-cell malignancies.

POSSIBLE CONTRIBUTING FACTORS LEADING TO TUMORIGENESIS

When designing a mouse model that can accurately recapitulate SMZL, it is imperative to understand all of the factors that may contribute to the tumorigenesis of the disease. To shed light on which factors specifically contribute to the occurrence of SMZL, a population-based study was conducted in the United States on a cohort from 2001–2008 on SMZL incidence and patient survival. Several possible contributing factors emerged from this study, including autoimmune disease (20% of cases), environmental factors, and aging-related effects, such as chronic inflammation, DNA damage, and a diminished immune response (1, 2). In addition to these, specific factors that might influence oncogenic events can include regulatory elements, infection, genetic mutations (transcriptomic), or epigenetics (methylation patterns).

Differences in disease drivers can distinguish SMZL into two different subtypes. Approximately half of SMZL cases are likely caused by infectious disease, more specifically, the hepatitis C virus [HCV; (3)]. This infectious disease-driven subtype suggests that virally transformed animal models might be an effective way to study disease onset and progression. However, chromosomal aberrations are present in the vast majority (>70%) of all SMZL cases, implying that a genetic component may serve as the major driver of tumorigenesis (4). Clinically, these two subtypes of SMZL are distinct in terms of disease progression and prognosis for patients.

Infections

Many studies suggest an antigenic role for tumorigenesis of SMZL. In fact, 30–40% of cases have shown to be disease driven (5). The possible causative role of HCV has been suggested both based on high prevalence as well as multiple epidemiologic and therapeutic studies (1, 3, 6). The etiology of HCV and its relation to B-cell lymphomas in general has been correlated to the geographic distribution in a few studies with small case numbers, mainly in Japan and Southern Italy. Overall, local HCV prevalence along with genetic and environmental factors may play a part in the geographically diverging results (3). Although geographic distribution has not yet been shown to have a significant impact on prevalence rates, an increase in HCV-positive persons from 2.7 million to 3.2 million from 1994–1998 to 1999–2002 mirrored increased prevalence rates of SMZL during this same time frame (2). Furthermore, from 2001 to 2008, the incidence of SMZL continued to steadily climb (2) and now comprises 2% of all lymphoid neoplasms (7). Although the exact pathogenesis mechanism is unknown, both chronic antigen stimulation and viral lymphotropism may contribute to progression of the malignant cell (3).

Findings that intraclonal diversification caused by ongoing somatic hypermutation was identified in 81% of the rearrangements using the *IGHV1-2*04* genes versus only 40% of rearrangements using other *IGHV* genes. This supports the idea of antigen selection in SMZL ontogeny, as well as the possibility of ongoing antigen involvement throughout the progression

of the disease, even possibly toward diffuse large B-cell lymphoma (DLBCL) like suggested in the “Multistep Theory of Lymphomagenesis” (7–10). The 14q32 band holds *IGHV*, and translocations involving the 14q32 band have been detected less frequently in SMZL than in non-Hodgkin lymphomas. Half of SMZL patients carry an increased load of *IGHV* somatic mutations, which is associated with improved prognosis (11). Combined, this supports the argument that *IGHV1-2*04* SMZL is, in fact, a distinct molecular SMZL subtype that needs to be recognized and studied *in vivo* (8–11).

Genetic Mutations

Although many SMZL cases have shown a possibility for a disease-driven etiology, more than 70% of SMZL cases show some form of chromosomal aberration, most predominantly a loss of heterozygosity (LOH) at 7q (2). This 7q LOH is observed in 40–50% of total cases, and the 7q31–32 deletion is present in approximately 45% of all cases, serving as the most common cytogenetic abnormality, thus suggesting a genetic driver (8, 9, 12–16). Many studies have been done in hopes of finding exactly which genes and pathways are altered in SMZL, therefore serving as potential targets on the development of SMZL murine models. A summary of these studies can be found in **Table 1** (8, 9, 11, 13–15, 17–25). Although many genes (most notably *NOTCH2*, *KLF2*, *KLF4*, and *BIRC3*) have been reported as mutated in SMZL, we suggest that the 7q deletion is of primary importance, as it is possible this deletion serves as a marker for disease progression and may even be a causative event, rather than a pro-survival function as was previously speculated (9).

Methylation Patterns

In a genome-wide DNA-promoter methylation profiling study by Arribas et al., two main clusters were distinguished based on the degree of promoter DNA methylation (15). This high-M cluster not only had an inferior outcome and showed high risk for histologic transformation to DLBCL but suggests that DNA hypermethylation could act together with 7q31–32 deletion, *NOTCH2* mutation, and *IGHV1-02*, to determine a distinct genetic and epigenetic subgroup of SMZL (11).

BIRDS OF A FEATHER: B-CELL NEOPLASMS CLL, MCL, AND SMZL

Chronic lymphocytic leukemia, MCL and SMZL are all neoplasms that affect mature B-cells; yet, in contrast to its B-cell counterparts, SMZL is the least studied. These three malignancies have major commonalities (27–30), including some shared surface markers, shared pathways for disease progression (15), and hypothesized infectious disease drivers, including HCV (**Figure 1**).

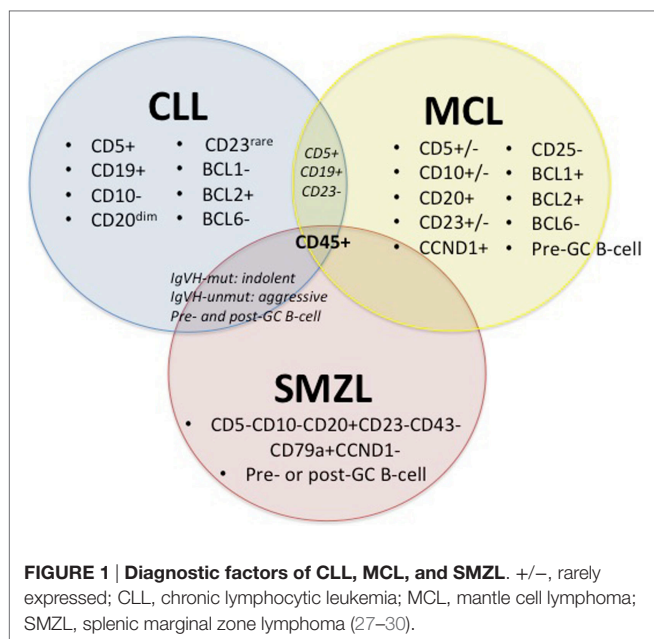

Figure 1 depicts immunophenotypical similarities and differences across CLL, MCL, and SMZL. The expression of CD5, CD19, BCL2, and rarely CD23 along with the absence of CD10 and BCL1 with diminished CD20 set CLL apart from its close

relatives. However, the presence of CD5 and CD19 and the absence of CD23 can also indicate MCL, so it is important to run a multitude of panels in order to solidify a diagnosis. MCL can display variable expression of CD5, CD10, and CD23 and express CD20, CCND1, BCL1, and BCL2, while lacking CD25 and BCL6. SMZL expresses CD20 and CD79a but lacks CD5, CD10, CD23,

CD43, and CCND1. Both CLL and SMZL are thought to originate from pre- or post-germinal center B-cells. This etiology differs from that of MCL, which is known to arise from pre-germinal center B-cells. Last, CLL and SMZL have a common prognostic factor with mutated *IGVH*, leading to improved outcome for patients (27–30).

EXISTING MURINE MODELS

The development and maintenance of murine models are important due to (i) difficulty in gaining access to patient samples, (ii) inability to study host:tumor interactions in an *ex vivo* system, and (iii) lack of cell lines that adequately recapitulate human disease (31). Both CLL and MCL have been well-characterized, including having murine models developed, while a dedicated, specific SMZL murine model driven by a transgene is still absent. Although previous SMZL models have been attempted, they often lead to development of DLBCL and, therefore, do not serve as true SMZL models (since clinically when SMZL progresses to DLBCL, additional transcriptomic events occur). The current murine models for CLL and MCL, as well as those identified to-date for SMZL are discussed below.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia is the most common adult leukemia in the Western world, and consequently, in comparison to its B-cell counterparts, murine models for CLL are the most well-defined. This is in part due to their ability to accurately recapitulate human disease, specifically the tumor microenvironment that is paramount for the maintenance of CLL cells. Because of this, it is imperative that CLL must harbor in supportive organs both in patients and in mouse models (31, 32). The most accurate recapitulation of CLL *in vivo* is arguably the E μ -*TCL1* transgenic mouse from the C. Croce lab (31), and this argument is emphasized in a review by Bresin et al. (33). Conversely, the NZB-*IRF4*^{-/-} model from R. Lu's lab is reminiscent of the aggressive phenotype of CLL (34). The NZB-*IRF4*^{-/-} mice developed spontaneous CLL at 100% penetrance – thereby indicating a relationship between levels of *IRF4* and CLL development.

In these mice, CLL cells with V_H11 proliferated predominantly in the spleen, thus allowing this model to serve as a successful study agent for molecular pathogenesis as well as for therapeutic techniques (35).

While the E μ -*TCL1* and NZB-*IRF4*^{-/-} lines most accurately recapitulate human CLL, cell line xenografts have also been established. Kellner and colleagues developed the first long-term proliferative cell line for CLL from a (del)17p case and furthered this development by using this cell line to create a xenograft model that recapitulates CLL (31, 36). These are major strides in CLL research, as no other group has been able to create a reliable, actively replicating CLL cell line. Other examples include xenografts of peripheral blood CLL and MCL cells in lymphoid mice by other labs (37, 38) thoroughly reviewed by Chen and Chiorazzi (39).

Not surprisingly, as CLL is the most common adult leukemia and receives the greatest amount of work by clinicians and scientists alike, major strides have been made to create reliable murine models for disease (including both the indolent and aggressive phenotypes).

Mantle Cell Lymphoma

Mantle cell lymphoma is an aggressive, yet rare, neoplasm that affects less than 200,000 people in the United States annually (10). In comparison to CLL cells, MCL cells are far less reliant on tumor microenvironment. Therefore, mouse models of MCL have largely come from xenografts that poorly mimic tumor microenvironmental conditions; however, MCL cells are less reliant on tumor microenvironment than CLL cells. By utilizing the method of tail vein injection, *in vivo* models of metastatic human MCL were established as described herein, briefly. Both primary cell lines from MCL cases and MCL cell lines (including Jeko-1, Mino, Rec-1, Hbl-2, and Granta-519) were used to generate disease in immunodeficient NOD.Cg-*Prkdc*^{scid} *Il2rg*^{tm1Wgl}/Szj mice or NOD.SCID mice (40–42). Hegde et al. (41) and Ahrens et al. (40) in the S. S. Joshi's lab created therapy-resistant models to study the impact of novel adjuvants for improving patient outcome. These xenografts were effective; namely, 7 out of 12 patient samples allowed for engraftment observation with the use of primary MCL cell lines, while all 5 of the MCL cell lines showed tumor engraftment. The overall survival of these mice varied with regards to the specific cell line used but ranged from 22 ± 1 to 54 ± 3 days (41, 42). Furthermore, the NOD.Cg-*Prkdc*^{scid} *Il2rg*^{tm1Wgl}/Szj MCL mouse model has been shown to aid in testing systemic chemotherapy, monoclonal antibodies, and angiogenesis inhibitors, which will serve as a significant tool in understanding this disease and advancing diagnostic and therapeutic techniques. Moreover, the NOD/SCID IL2R γ null xenograft model was effective for studying *p53*-mutated CLL and *ATM*-mutated MCL (38).

Taken together, these studies have led to recapitulation of MCL (both from primary cells and cell lines) *in vivo*, thereby providing effective murine models to use for drug testing as well as to increase the understanding of basic disease biology and disease progression.

Splenic Marginal Zone Lymphoma

Like MCL, SMZL is a rare neoplasm. Due to its relatively recent identification, it is not surprising that many questions linger about its oncogenesis and pathogenesis. SMZL has been observed spontaneously in a few murine models, namely, *NFS.N* mice expressing murine leukemia virus (5, 43, 44) as well as a transcription factor-induced transgenic line with murine leukemia virus (45). Although the latter model develops SMZL, it quickly progresses into full-blown DLBCL. Similarly, the loss of a potent tumor suppressor, *p53*, leads to a SMZL-like phenotype in mice (46). All of these mouse models aiming to recapitulate human SMZL *in vivo* include a viral component or a major genomic hit that is non-reminiscent of the human presentation.

An *in vivo* murine model to mimic SMZL remains to be created, but because of its potential at assisting hematologists in understanding basic B-cell biology, germinal center reactions, and ultimately tumorigenesis, a new model is most certainly warranted. The recent identification of the role for the 7q31-32 region, a common minimally deleted region in human cancers, reignites the efforts to pursue causative mutations in a coding or non-coding region within that locus.

LOH AT 7q31: POTENTIAL FOR MURINE MODEL DEVELOPMENT TO MIMIC SMZL

There are many regions of the genome considered “fragile” sites, and the long arm of chromosome 7 is one such region. Some studies have mapped the specific portions of this region that show causality with tumorigenesis, but others have simply recognized the region as a whole. LOH is observed at 7q31-34 in the following cancers: SMZL, meningioma, papillary thyroid carcinoma, ovarian cancer, acute myeloid leukemia, myelodysplastic syndrome, and pancreatic carcinoma. Deletions at 7q have been reported in a variety of human neoplasias including leukemia, breast, ovary, colon, prostate, gastric, head and neck, pancreatic, and renal cell carcinomas (47).

Several groups have sought a “master regulator” within the commonly deleted 7q region (and corresponding downregulated genes) in severe cases of SMZL. However, despite valiant efforts at well-controlled experiments (9), a master regulator has yet to be identified. The development of such a model to explore driver mutations leading to SMZL would shed light on SMZL pathophysiology as well as biological behavior, thereby serving as an effective model.

A Role for Cav1

Fragile site FRA7G holds two tumor suppressor genes, including *CAV1* and *TES*. Cav1 has been shown to serve as an oncogene or tumor suppressor depending on cell or tissue type, microenvironmental influence, or disease progression (48). *CAV1* 7q31.2 deletions/translocations appear to be downregulated in ovarian, lung, and mammary tumors while upregulated in prostate, bladder, thyroid, and esophageal carcinomas (47). Haploinsufficiency of *CAV1* is enough to induce partial transformation of human

breast epithelial cells (49). Additionally, the loss of *Cav1* combined with MMTV-PyMT leads to the acceleration of mammary tumors (47). *Cav1*-knockout mice do not spontaneously develop tumors, although the skin is more susceptible to chemical carcinogenic treatment. Specifically, when *Cav1*^{-/-} mice were exposed to 7,12-dimethylbenz(a)anthracene, epidermal cells significantly upregulated *CCND1* and *ERK1/2* and mice developed hyperplastic ductal epithelium (47, 50).

In addition to carcinogenic challenges in *Cav1*-null mice, recent studies identify a link between *Cav1* and both B- and T-cell neoplasms. Specifically, *CAV1* was identified as a major immunoregulator, which was significantly upregulated in aggressive CLL cases (48). When Eμ-*TCL1*-*Tg-Cav1*^{-/-} mice were generated, they displayed a significantly more aggressive phenotype than the indolent Eμ-*TCL1* model (51). Moreover, the role of *Cav1* is well-documented in immune synapse formation (48, 52), thereby suggesting another contribution to immune evasion and tumorigenesis. Most recently reported, *CAV1* is deleted in up to 45% of SMZL cases (16). Additionally, *CAV1* has been documented to play a key role as a potential diagnostic marker in T-cell malignancies as it is significantly upregulated in more than 67% of T-cell malignancies (53). Taken together, these data suggest a clear role for *CAV1* in both B- and T-cell neoplasms. Therefore, as *CAV1* is lost or mutated in up to half of all SMZL cases and the 7q region (where *CAV1* is located) is commonly deleted, we suggest that a murine model under an oncogenic driver, coupled with *Cav1* LOH, could be an effective model.

SUMMARY

CAV1 resides at the 7q region and is heterogeneously expressed in cancer. Specifically, *CAV1* is downregulated in SMZL cases, while upregulated in aggressive cases of chronic lymphocytic leukemia and five types of mature T-cell lymphomas. We (and others) have demonstrated a critical role for *CAV1* in immune synapse formation, cellular proliferation, and cellular migration. *Cav1*^{-/-} mice are immunosuppressed, but the mechanism by which this immune dysregulation occurs is currently unknown. Improving our understanding of the basic biology of *CAV1* in the immune response will translate to (i) determining its role in the immune response governing antigen-presentation events in healthy and diseased immune responses and (ii) how *CAV1* controls immunophenotype/immune cell frequency. We have shown *CAV1* to be significantly dysregulated across more than 67% of cases of mature T-cell lymphomas as well as in aggressive cases of chronic lymphocytic leukemia. Recent data from others identify the 7q deletion in another mature B-cell lymphoma: SMZL. Therefore, results generated from this proposal would be applicable across lymphoid neoplasms. Taken together, our preliminary data support a hypothesized role for *CAV1* in lymphoid tumor progression, likely through an immune regulatory method.

Based on the knockout studies involving *p53*, coupled with the high incidence of spontaneous Hodgkin's lymphoma development on the Swiss Jim Lambert mice, we suggest the

development of a SMZL murine model with *Cav1* LOH with or without an oncogenic driver, such as *p53*^{-/-} or *MYC-Tg*. Finally, the *CAV1* deletion being present in up to 45% of all SMZL cases suggests that generating a *MYC-Tg-Cav1*^{-/-} mouse could serve as a more representative clinical mimic of SMZL. Based on the known role of *CAV1* in aggressive cases of both B- and T-cell malignancies, its role in immune regulation through immune synapse formation, its role in the tumor microenvironment, and the frequency of LOH at 7q, we suggest that this deletion could serve as a marker for disease progression and may even be a causative event.

AUTHOR CONTRIBUTIONS

Both CP and CC conceptualized, wrote, and edited the manuscript and approved this final version.

FUNDING

The authors acknowledge the Department of Biology and the College of Arts and Sciences at the University of Nebraska at Omaha and the University of Nebraska Foundation for supporting this work.
