INTRODUCTION

• Over 35% of Americans suffer from balance disorders [1].
• Improved quantitative and low cost analysis of these disorders is necessary.
• The goal of this project is to develop a solution to the problems of expensive equipment and lack of quantitative data in balance assessments using smart phone sensors.
• The project aims to improve upon existing standing balance testing and validate a system for dynamic testing.

METHODS

• A mobile application has been developed to walk the user through the six stances of the BESS balance test (Figure 1), as well as a six minute walking trial.
• The smart phone is strapped to the users waist and collects tri-axial acceleration and angular velocity data.

RESULTS

• Sample Entropy (SE), a non-linear method of quantifying static stability, is used to observe variability of the subjects’ static postural sway during each of the six BESS stances.
• Maximum Lyapunov exponents (LyE), a non-linear method of quantifying dynamic stability, are calculated to quantify dynamic movement from the six minute walking test.
• Balance data is analyzed external to the application using custom MATLAB code. The middle 30 seconds of walking data is analyzed to facilitate compare with similar studies [2].

• The average greatest LyE, or least stability, was found in the medial-lateral direction (Figure 2).

• Values calculated from mobile phone data proved to be slightly higher than previous studies using an XSENS system [2]. This is likely due to the amount of noise in the low quality mobile accelerometer sensors.
• Average SE of all 11 subjects is shown for each of the six BESS balance stances (Figure 3).

DISCUSSION

• Smart phone technology has proven to be promising using more sophisticated, nonlinear analysis and in the use of dynamic testing.
• This experiment has expanded current systems to assess dynamic walking balance, which may have increased relevance to risk of falls.
• Previous research has shown the potential for smart phone sensors to collect continuous data to diagnose balance disorders, however, validation and more sophisticated sensor fusion is lacking [4].
• We believe a low cost, accessible, yet sophisticated system can enhance the detection of balance problems and aid in early identification of risk and disorders.
• Future studies will investigate balance performance in unhealthy individuals.
• Future work will collect more subjects to establish healthy baseline data.
