INTRODUCTION
- Parkinson’s disease (PD) impacts executive and motor function1. Walking requires executive function and attention2, but performing a secondary task while walking (i.e., dual-tasking) can impact the performance on one or both tasks3.
- Locomotor function is reflected in stride-to-stride fluctuations, notably by the amplitude (coefficient of variation)4 and the temporal organization (scaling exponent α-DFA)5 of stride time intervals.
- Primary aim: To determine the effect of an attention-demanding task on gait variability in people with PD.

RESULTS
- We have collected so far 19 people with Parkinson’s disease (age 68 ± 4.6), and 4 healthy elderly (age 67 ± 5.0). We only report results from PD here.
- When listening to an audiobook:
  - PD participants walked slower (- 0.02 m/s)
  - Gait variability in PD patients was more random (mean difference of DFA values = 0.07, p = 0.018).
  - Gait steadiness did not significantly change (mean difference of CV values = 0.11 %, p = 0.203).

METHODS
- 40 people with Parkinson’s disease (age>60), and 40 age and gender matched healthy elderly (HE) will participate in the study. All participants will perform three conditions in random order:
  - Seated Audio Trial
  - Normal Walking Trial
  - Dual-Tasking Trial
- Audio trials involve
  - Listening to an audiobook (different between seated and walking trials)
  - Monitoring 2 predefined words
  - Answering 10 questions about context

DISCUSSION
- People with PD maintain their walking speed from single to dual-tasking, at the cost of more random variability. This potentially reflects increased control of locomotion. In contrast, gait steadiness (CV) is not affected by dual-tasking.
- Walking does not seem to alter patient’s performance on the cognitive task. This suggests that they prioritize the cognitive task, while controlling more their step-to-step variations.
